# Screening Residential Tracts for Agricultural Activity

Ralph V. Matthews

SCREENING RESIDENTIAL TRACTS FOR AGRICULTURAL ACTIVITY, by Ralph V. Matthews, Research and Applications Division, National Agricultural Statistics Service, U.S. Department of Agriculture, Washington, D.C. 20250, April 1988. Staff Report No. SSB-88-05.

#### ABSTRACT

The National Agricultural Statistics Service screened residential tracts in the area frame sample using subsampling procedures in 1986 and 1987. In 1986, tracts with more than 10 residences were re-screened 3 months after the June Enumerative Survey (JES). In 1987, tracts with 2 or more residences were screened during the JES. Subsampling resulted in farm number estimates which were more unbiased than the operational JES estimates and exceeded the JES estimates by 5.4 and 6.3 percent in 1986 and 1987, respectively. Subsampling may not be the ideal screening procedure for NASS, but efforts should continue to replace the operational "skip technique."

KEY WORDS: area frame sampling, household survey, residential screening

#### ACKNOWLEDGMENTS

Mike Steiner helped with the analysis of the 1987 data and the organization of the report. Jack Nealon, Ron Bosecker, and Phil Kott made suggestions which clarified the presentation of the results.

#### SUMMARY

The National Agricultural Statistics Service (NASS) screens densely populated residential tracts of the area sampling frame to locate Resident Farm Operators (RFO's). Screening ensures that the tracts are surveyed completely for agricultural activity.

In 1986 and 1987, the National Agricultural Statistics Service screened residential tracts in the area sampling frame more intensely than in previous years. The impetus for the enhanced screening was the Census Bureau's need for an area-based estimate of farm numbers to adjust for list frame incompleteness during the 1987 Census of Agriculture.

In 1986, the process was a re-screening and subsampling of tracts with more than 10 residences done 3 months after the June Enumerative Survey (JES). The number of RFO's found through rescreening was significantly greater than zero. The two surveys (JES plus re-screening) resulted in a farm number estimate which was 5.4 percent greater than the operational JES indication at the national level. The mean square error (MSE) from the JES was approximately 8 times larger than the MSE from the combined surveys, due to the bias in the JES estimate.

In 1987, the screening was incorporated into the JES and done in tracts with 2 or more residences. Census Bureau screening techniques required the tabulation of all residences in a tract and the selection of a subsample of residences to contact. Enumerators conducted interviews at the selected residences and also asked the respondents if any farm operators lived in the neighborhood. The number of farm operators was expanded by the segment expansion factor and transmitted to the Census Bureau.

An alternative farm number indication was produced using the additional level of expansion based on the subsampling rate within a tract but ignoring any referrals within the neighborhood. The alternative estimates were greater than or equal to the JES estimates in all states and 6.3 percent greater nationally. A nonparametric comparison of the two indications was significant at the 1 percent level.

The analysis in this report showed that subsampling and within-tract expansion were superior to the "skip technique" in a statistical sense. Unfortunately, although subsampling is more defensible statistically than the "skip technique," it will not be used in the 1988 JES due to its cost. Even though subsample screening has been viewed as a nonviable solution to NASS's screening problems, efforts should continue to replace the "skip technique."

#### SCREENING RESIDENTIAL TRACTS FOR AGRICULTURAL ACTIVITY

#### By Ralph V. Matthews1

#### INTRODUCTION

The National Agricultural Statistics Service (NASS) screens densely populated residential tracts in the area sampling frame to find Resident Farm Operators (RFO's). Screening ensures that the tracts are surveyed completely for agricultural activity.

NASS screens with the "skip technique," in which enumerators contact at least 1 out of every 10 residences in the built up tracts to inquire about farm operator status [3]<sup>2</sup>. Enumerators also ask if the respondent knows any other residents of the tract who operate a farm. An interview is conducted with all potential RFO's. If the operation has a potential of at least \$1,000 of annual sales, the respondent is an RFO. The residence and operated land in the segment constitute an agricultural tract, and the number of RFO's is expanded to estimate number of farms.

In preparation for the 1987 Census of Agriculture, the Bureau of the Census asked for verification that NASS's screening procedures did not miss substantial numbers of RFO's. The question arose because the Bureau's techniques for locating respondents are more defensible statistically than those of NASS. In Census Bureau screening, a map or list of the residences is prepared, and a subsample of residences is selected with the sampling rate based on the total number of residences in the tract. The Bureau wanted NASS's area-based estimate of farms to adjust for the incompleteness of its list frame.

The intensive screening also allowed NASS to compare the operational RFO totals versus RFO totals based strictly on subsampling. This report describes the comparison and the results of the 1987 screening.

#### 1986 RESIDENTIAL SCREENING

In September 1986, all tracts from the 1986 June Enumerative Survey (JES) with more than 10 residences were screened by NASS enumerators using subsampling procedures. Instructions were provided to enumerators in an Interviewer's Manual [4]. The purpose was to learn if RFO's were missed by the screening in the 1986 JES. This was a pilot test of the enhanced screening methods before their operational use during the 1987 JES.

<sup>1</sup> Mathematical statistician with NASS, USDA.

<sup>2</sup> Bracketed numbers cite references at the end of this report.

The total number of RFO's was estimated by two components: the JES estimate and the re-screening estimate.

Ytotal = Yjes + Yre-screen .

Both  $Y_{jes}$  and  $Y_{re-screen}$  were calculated by summing the expanded segment totals over all strata. The re-screening estimate included the within-tract expansion based on the subsampling rate.

The standard error of the total was the square root of the following variance:

Var[Ytotal] = Var[Yjes + Yre-screen]
= Var[Yjes] + Var[Yre-screen]
+ 2 Cov[Yjes , Yre-screen] .

The covariance was calculated between the expanded segment totals for each estimate within each substratum. The two surveys did not produce independent estimates of farms, since the tracts to re-screen were identified from the results of the JES.

Table 1 contains the farm number estimates from the 1986 JES, the September 1986 re-screening, and the combination of the two surveys. The number of additional farms estimated by re-screening was 5.4 percent of the total JES estimate. Moreover, it was 4 times greater than its estimated standard error, indicating that the number of RFO's found by re-screening was significantly greater than zero.

The state-level correlation coefficients between the number of RFO's found by the JES and by the re-screening are also shown in table 1. The correlation was positive if both surveys found RFO's in the same segment. The correlation was negative if only one survey found RFO's in a segment and only the other survey found RFO's in a different segment. The correlation was zero if one survey found RFO's in a segment and the other survey found none.

Correlations could not be computed for the 20 states which had no standard error of the re-screening estimate. In the remaining 28 states, 9 correlations were negative and 6 correlations exceeded .1 and were positive. Overall, the correlation results indicated a poor relationship between the surveys in their abilities to locate RFO's.

In order to compare the accuracy of the two surveys, the mean square error (MSE) was calculated for each. Since the total estimate was assumed unbiased, its MSE equaled its variance. The MSE for the JES estimate had two parts: its variance and its squared bias.

The total number of RFO's was estimated by the JES estimate plus the re-screening estimate:

$$Y_{total} = Y_{jes} + Y_{re-screen}$$
or  $t = j + r$ .

By definition, the variance of r is

$$VAR(r) = E \left[ \begin{array}{c} 2 \\ r \end{array} \right] - R^2$$

where E is the expectation operator and R is the parameter value. This leads to the equality

$$R^{2} = E \left[ \begin{array}{c} 2 \\ r \end{array} \right] - VAR(r) ,$$

which will be used below. The bias in j is equal to R. Thus, the Mean Square Error of the JES estimate is

$$MSE(j) = VAR(j) + \begin{bmatrix} Bias & in & j \end{bmatrix}^{2}$$

$$= VAR(j) + R^{2}$$

$$= VAR(j) + E \begin{bmatrix} 2 \\ r \end{bmatrix} - VAR(r)$$

This last value can be estimated in an unbiased fashion by

$$^{\circ} \qquad ^{\circ} \qquad$$

The ratio of the JES MSE to the total MSE at the national level was 7.87, indicating much less accuracy from the JES estimate than from the total estimate. Approximately 95 percent of the JES MSE was due to the squared bias term.

The state estimates told a different story. Compared with the total MSE, the JES MSE was greater in 8 states, less in 16 states, and approximately equal in 4 states. This suggested that the re-screening process as conducted in 1986 was too unstable to produce viable estimates at the state level. Nevertheless, the JES estimate had a very large bias at the national level. The phenomenon of variance dominating bias in small samples and bias dominating variance in large, aggregated samples is not uncommon.

#### 1987 RESIDENTIAL SCREENING

The 1986 results showed that RFO's were missed in the screening for the JES. The screening methods used in September 1986 were made operational in the 1987 JES with the following modifications:

- 1. Tracts with 2 or more residences were screened.
- 2. Vacant residences, inaccessibles, and refusals were replaced by substituting other residences.
- 3. Each respondent was asked if anyone in the neighborhood operated a farm, operated a ranch, or stored grain. Potential RFO's found with this question were known as referrals.
- 4. In non-agricultural strata, 308 segments that would normally have rotated out of the area frame sample were not rotated out. This resulted in a one-time larger sample size, because new segments were rotated into the sample as usual.

The objective of the subsampling was to provide improved farm number estimates to the Census Bureau. The residences to contact were identified through subsampling, and potential RFO's were interviewed to verify their status. RFO's found with the neighborhood referral question were included in this estimate. The tract totals were summarized in the usual way, having no within-tract expansion. This JES indication of farm numbers was reported to the Census Bureau.

Since counts were available for residences per tract and residences sampled per tract, a within-tract expansion factor was calculated to produce an alternative farm number estimate. In tracts with RFO's, these expanded tract totals replaced the tract totals in the JES data before re-summarization. RFO's found with the neighborhood referral question were not included in this estimate, since the subsampled residences represented all residences in the tract. This was an additional indication considered by the Agricultural Statistics Board of NASS when the farm number estimates were set in July 1987.

Instructions and examples were provided to enumerators in a supplement to the JES Interviewers Manual [5]. Tables in appendix 1 show the state totals of tracts screened and residences contacted. The forms used for the residential screening are shown in appendix 2.

Table 2 shows the unexpanded numbers of RFO's and expanded numbers of farms found by the residential screening. For example, the 5 RFO's in Iowa expanded to 9,547 farms at the state level. Only those RFO's found by initial contact or substitution are included; referrals within the neighborhood are not included.

In Florida, New Jersey, Texas, and West Virginia, 10 or more RFO's were found. In Florida's sample, 20 segments (4.7 percent) were not rotated out in 1987. This was the largest sample size change in absolute number and in percentage of the sample. The New Jersey frame was new in 1987, and the residential tracts may have been screened more thoroughly in the first year of use.

Table 3 contains two sets of farm number estimates based on the 1987 JES. One set is from the operational JES summary; the second set includes the expansion based on the subsampling within each tract. Overall, a 6.3 percent increase resulted from expanding subsampled RFO's. The two national estimates in table 3 and a multiple-frame estimate were considered by the ASB in setting the national farm number estimate at 2,173,410 farms [6].

The subsample expansion estimate exceeded the JES estimate, unless the number of RFO's found with the neighborhood referral question equaled the expanded number of RFO's using the withintract expansion factor. The number of potential RFO referrals was 103, and 7 were confirmed as RFO's. The small number of referrals ensured that the tract expansion estimate exceeded the JES estimate if RFO's were found.

The JES and the tract expansion estimates were compared to determine if the JES estimates were biased downward in a significant number of states. Substituting for vacant residences may have caused a slight bias, but it was believed to be ignorable. In 34 of 48 states, the JES estimate was less; in 14 states, the estimates were equal. A conservative sign test indicated that the probability of 34 out of 48 tract expansion estimates exceeding the JES estimate, when one estimator was not expected to produce larger numbers than the other, was less than 1 percent. The downward bias in the JES estimates resulted from the failure of the neighborhood referral question to find enough RFO's to balance the within-tract expansion factors.

TOTAL			:	151

Table 5 contains estimates of the number of residences in all tracts and estimates of the number of residences in the subsampled tracts (2 or more residences). At the national level, 89 percent of the residences in all sample tracts were in the tracts screened.

The Census Bureau report "Housing Vacancies, Second Quarter 1987" [1] contains estimates of total residences which can be compared with the NASS estimate of 85.6 million residences. The Census Bureau estimate of all housing units was 101.6 million, and the estimate of occupied housing units was 90.2 million. Individual state estimates were not published. The NASS screening procedure was to count all housing units, including vacant ones. Thus, the NASS estimate was 15.7 percent below the Census Bureau estimate.

Table 5 -- Estimates of number of residences using all tracts and only subsampled tracts; 1987 JES residential tract screening

 $<sup>^{1}\,</sup>$  One segment, divided in 4 equal parts after the 1986 JES, accounted for 59.2 percent of the residences in subsampled tracts.

\_ \_ \_ 10

#### CONCLUSIONS AND RECOMMENDATIONS

In 1986, re-screening after the JES resulted in an RFO estimate which was 5.4 percent greater than the JES estimate. The RFO estimate from re-screening was significantly greater than zero when compared with its standard error. The MSE of the national JES estimate was approximately 8 times greater than the MSE for the combined estimate.

In 1987, the screening process was incorporated into the JES, but separate RFO estimates were calculated with and without the within-tract expansion. The subsample screening resulted in an estimate which was 6.3 percent greater than the JES estimate.

In 34 of 48 states, the operational JES estimates were less than those incorporating the within-tract subsampling rates, due to the failure of the neighborhood referral question to locate many RFO's. This highly significant result confirmed a downward bias in the operational JES estimate.

NASS's two-year experiment with enhanced residential screening ended after the 1987 JES. The Census Bureau's data needs for the 1987 Census of Agriculture were met, and the high cost of enhanced screening could not be justified on an ongoing basis. The "skip technique" used prior to 1987 will be used in the 1988 JES [2]. The number of urban segments will return to levels comparable to 1986, as the urban segments which were kept in for the 1987 JES will be dropped [7].

The successful use of subsample screening has implications for future JES surveys. Data from JES surveys in the two years showed subsampling to be preferable statistically to the "skip technique." High costs prevented the adoption of subsampling as an operational procedure, but the "skip technique" was shown to be inferior. Efforts should continue to find a replacement procedure.

# APPENDIX 1 Description of subsampling procedure, 1987 JES residential screening

In 1987, to sample the residences in a tract, all residences were listed, and a random start was selected. The sampling intervals in table A1 were followed after the random start.

Table A1 -- Sampling rates of residences per tract; 1987 JES residential tract screening

	ide tra	nces ct	:	Sampling rate
1 4 26	- -	3 25 50	:	all every 4th every 8th
51	>	100 100	:	every 15th every 25th

Table A2 contains the total number of sampled tracts in each state, the number of non-agricultural tracts with only one residence, and the residential tracts which were screened. The one-residence tracts were not meant to be screened, but 56 actually were screened. Approximately one-third of all sampled tracts (42,918 of 128,028) were non-agricultural tracts.

At the national level, 8.6 percent of all sampled tracts were screened. Table A2 shows that 38,028 of the 315,712 residences in the screened tracts were to be contacted -- a 12.0 percent sample. This is slightly above the 10 percent sample which was the goal of the earlier NASS screening methods.

Table A3 shows the frequency distribution for the number of residences in the screened tracts. For example, 3.8 percent of Alabama's 238 sampled tracts had from 1 to 3 residences in the screened tracts. Overall, the average number of residences in the screened tracts was 29. At the national level, 49 percent of all tracts had from 4 to 25 residences. This was also the modal class in 40 of the 48 states.

Table A4 shows the frequency distribution for the number of residences to contact in the screened residential tracts. For example, 61.8 percent of the tracts screened in Alabama had from 1 to 3 residences contacted. Overall, the average number of residences contacted in the screened tracts was 3.5. Enumerators rarely had to contact more than 6 residences per screened tract.

Table A5 contains an approximate accounting of the residences which were screened. "Residences to contact" are those residences identified to be contacted when the screening process began. "Non-RFO substitutes" are residences substituted for initial contacts which were then found not to be RFO's. "Neighborhood referrals" are those residences found through the question about agricultural activity by others in the neighborhood. Seven of these 102 referrals were RFO's. The "Potential contacts" column is the sum of the first three columns and reflects the potential number of contacts. "Residences contacted" may exceed "Potential contacts" due to an initial inaccurate count of residences in the tract.

Table A5 has the national totals with and without Minnesota's data. More than 600 residences were contacted in Minnesota, but the data was transmitted as only one observation per tract. Thus, the national "potential contacts" and "residences contacted" figures are misleading if Minnesota's data are included. This problem had no effect on the farm number estimate, since no RFO's were found in Minnesota through screening.

The 151 RFO's from table 2 are not identified as a distinct group in table A5. They are either included in the initial "Residences to contact" or are substitutions that do not appear in table A5 since only non-RFO substitutions were coded. True RFO's were coded the same whether they were initial contacts or substitutes, so they could not be separated.

Table A2 -- Total sampled tracts, single-residence non-agricultural tracts, residential tracts screened, residences in screened tracts, and residences to contact; 1987 JES residential tract screening

## GRID ( 1 of \_\_\_\_)

Sketch tract boundaries and location of residences within the tract. Label roads and other land-marks which form tract boundaries. Identify residences by house number, if available, or in some other consistent manner. Schools, factories, etc., that may be located in the tract should also be sketched.
